Introduction

Coronary artery anomalies comprise a heterogeneous group of rare congenital heart defects, being classified according to their origin, course and distal bed, with an incidence ranging between 0.3% and 1.5% in the overall population. Dodge-Khatami et al. subdivided them into seven categories, according to their clinical complexity: coronary arteries originating from the pulmonary artery, coronary arteries with anomalous aortic origin, congenital atresia of the left main coronary artery, coronary arteriovenous fistulas, coronary arteries forming myocardial bridges, coronary artery aneurysms and coronary stenosis. The Texas Children’s Hospital classification uses angiotomography with virtual angioscopy and divides the classification into three topics: origin of the anomalous coronary artery, coronary artery course and ostium morphology. From the viewpoint of anatomical risk, the anomalous left coronary artery with an interarterial course, presence of intramurality and a slit-like ostium are the main predictive factors of severity.

A specific type is the anomalous origin of the left coronary artery from the right coronary sinus with an interarterial course, which is associated with hard outcomes in approximately 60% of the cases. Clinically, patients may present with nonspecific symptoms, ranging from palpitations, chest pain, post-exertion syncope or remain asymptomatic throughout life, with sudden death being the first and only manifestation of this condition.

Most cases have been reported in young male individuals, but there is no scientific evidence yet whether the incidence is actually higher in males, or if this gender is more often diagnosed by performing more intense physical activities, therefore triggering symptoms.

The most common of these conditions is the anomalous origin of the left coronary artery from the pulmonary artery. However, we present herein a case with an anomalous origin of the left coronary artery from the right coronary sinus, with a proximal course between the aortic and the pulmonary arteries in a 31-year-old man.

Case report

A previously healthy 31-year-old male patient, a mason, was admitted to the Emergency Unit in October 2012, complaining of palpitations and cold sweats, with hypotension (BP = 90 x 50 mmHg), which developed into syncope at the hospital unit. He was submitted to the first electrocardiogram (Image 1A), which disclosed sustained monomorphic ventricular tachycardia (SMVT). He underwent electrical cardioversion and was transferred to intensive care unit (ICU) for clinical stabilization.

Therapy with amiodarone was started in the ICU, with some episodes of slow ventricular tachycardia (VT) and periods of accelerated idioventricular rhythm (Image 1B), albeit asymptomatic. He reverted to sinus

Ventricular arrhythmias comprehend a spectrum that range from ventricular extrasystoles, VT, to ventricular fibrillation. Ventricular fibrillation is the one most frequently associated with acute coronary syndrome. On the other hand, the SMVT has as its electrophysiological mechanism of re-entry related to scarring due to structural heart disease (e.g., previous infarction and Chagas’ disease). In the younger population - children, adolescents, and young adults - with sustained episodes of VT, the condition is usually due to diseases that manifest early in life, including genetically-determined arrhythmias, acute myocarditis, and congenital heart disease – among the latter, coronary artery anomalies.5

Congenital anomalies of the coronary arteries may result in benign or malignant clinical consequences depending on their course and origin.2 They are usually classified into four groups: according to the coronary origin and course (absent left main coronary artery, anomalous location of the coronary ostium inside or outside the appropriate Valsalva sinus, anomalous location of the coronary ostium in the inappropriate Valsalva sinus and single coronary artery); intrinsic to the coronary anatomy (stenosis or atresia of coronary ostia, coronary aneurysm, coronary hypoplasia and myocardial bridge); anomalies of terminal coronary circulation (fistulas into cardiac chambers, inferior vena cava or pulmonary arteries and veins); and anomalous anastomotic vessels.2

The anomaly described in this case is that of the left coronary artery originating from the right coronary sinus, a rare congenital abnormality, with a prevalence of 0.15% in the overall population.6 This anomalous coronary artery is most commonly related to sudden death (59% of cases), usually preceded by physical activity (in 81% of these cases). The cases in which the coronary artery courses between the aorta and the pulmonary trunk during exercise, leading to myocardial ischemia.27,8 When only the origin is anomalous, but the coronary artery does not follow this course, there is no risk of sudden death.4 In general, the pre-pulmonary, subpulmonary or retroaortic courses are considered benign.3,4

In general, most patients remain asymptomatic or exhibit symptoms only after strenuous physical exercise, which may have a fatal outcome in these cases. Clinical presentation ranges from palpitations, dyspnea, chest pain and syncope to sudden death,6,7 being the second leading cause of sudden death in young individuals.26 Basso et al.5 reported that only ten (36%) of the 27 cases with sudden death (23 anomalous left coronary arteries and four right coronary artery anomalies from the
opposite Valsalva sinus) had symptoms before the event, including syncope, chest pain and palpitations. All cases had an acute-angled outflow and a slit-like ostium.5

Due to the varied and nonspecific symptomatology, clinical suspicion and detailed investigation are necessary. Thus, a 12-lead electrocardiogram, exercise testing and an echocardiogram are suggested for the initial approach of symptomatic patients, which in some cases may suggest the diagnosis or disclose another cause for the symptoms.

Subsequently, a coronary angiotomography and a coronary angiography should be performed for diagnostic confirmation.7 In cases of symptomatic patients, surgical revascularization is the therapeutic indication, especially when the left coronary artery originates from the opposite coronary sinus and courses between the aorta and the pulmonary artery, due to the risk of coronary compression by the larger-caliber vessels.4,9 There is no consensus regarding the treatment of the anomalous anatomy with no evidence of ischemia or with an intramural course.
or ostium anomaly. The management tends to be more conservative, with the use of beta-blockers and changes in lifestyle, aiming to avoid strenuous physical exercises. Therefore, the anomalous origin of the coronary artery is a group of rare congenital cardiac malformations with variable presentation. Due to the possibility of a lethal prognosis, it is necessary to identify the target population to establish screening methods to attain an early diagnosis of the anatomical alteration. Because it is more frequently associated with sudden death, a protocol should be established for young individuals practicing highly competitive sports or those subject to strenuous physical activities, aiming to prevent such an outcome. The diagnosis should always be recalled in cases of ventricular tachyarrhythmias with no other apparent cause, being a challenge for clinical practice, since this is a silent condition, but with definitive surgical treatment.
