Abstract

Background: Depression and hypertension are highly prevalent among elderly people. Although the relationship between these conditions is well recognized, however, the factors that may influence such association are not clearly understood.

Objective: To analyze the association between depression and hypertension in community-dwelling elders.

Methods: Two-hundred and thirty-one community-dwelling elders provided information regarding the following variables: sex, age, ethnicity, smoking habit, physical activity level (PA), body mass index (BMI) and diabetes mellitus (DM). These variables can potentially influence depression and hypertension, as well as its relationship. Screening for depression was made using the Geriatric Depression Scale (GDS). The presence of hypertension was defined based on self-reported data and/or the use of antihypertensive drugs. The logistic regression technique was applied, using hypertension as the dependent variable and depressive state as a predictive variable. Logistic regression was applied with and without adjustment for the potential intervening variables.

Results: The prevalence of depressive state and hypertension in the studied population was 14% and 59%, respectively. The association between depression and hypertension without adjustments was not significant (odds ratio [OR] = 2.28, 95% confidence interval [95%CI] = 0.98 - 5.32; p = 0.06). However, after adjusting for PA, BMI and DM, the strength of association between depression and hypertension significantly increased (OR = 3.08, 95%CI = 1.12 - 8.46; p = 0.03).

Conclusion: The association between depression and hypertension in the elderly is directly influenced by PA, BMI and DM. This finding may guide strategies to increase the adherence to a healthier lifestyle. (Int J Cardiovasc Sci. 2019;32(4):355-361)

Introduction

Senescence is a natural life process associated with increased risk of non-communicable diseases, as hypertension. In fact, there is a growing prevalence of hypertension with increasing age. This is worrying, since it is expected that the world population over 60 years old will be approximately two billion in the next decades and the prevalence of hypertension could reach up to 80% among elders.
Hypertension is recognized as a multifactorial clinical condition, with lifestyle-related factors, such as smoking, high sodium intake, sedentary lifestyle, among others, widely associated with this condition. However, recent studies have pointed to a close relationship between hypertension and depression, which becomes even more worrying when considering the elderly people, due to the known association between depression and aging.

Depressive disorder is common among the elderly; it is a multi-causal condition, whose etiology may vary from depressive disorders, observed in young adults, to those associated with chronic age-related processes (cardiovascular, inflammatory, endocrine, autoimmune processes), continuous use of some medications, psychological adversity, and cognitive deficits. Approximately 10% of individuals over 60 years old require therapeutic intervention for depressive disorder, and the prevalence of depression may be greater than 40% among elders living in geriatric institutions.

Changes in autonomic nervous system control, characterized by worse vagal control and increased heart rate, are observed in depressive subjects and are pointed out as factors that may explain the predisposition to hypertension. In addition, it is known that, among elders, the association between depression and hypertension seems to be influenced by obesity.

The study by Long et al., raises an important perspective in the understanding of the relationship between depression and hypertension among elders. In fact, Meng et al., had already reported that variables such as gender, race, smoking, physical activity level, obesity/body mass index (BMI), DM and other psychological factors are potentially confounding variables in the relationship between depression and hypertension. In this context, the present study aimed to analyze the association between depression and hypertension in community-dwelling elders, as well as to analyze the influence of confounding variables that are potentially capable to influence this association.

**Material and methods**

**Sample**

All community-dwelling old adults (≥ 60 years old) from Aiquara, Bahia, Brazil were invited to take part in this survey study. Two hundred eighty-nine subjects were screened, all of them answered an extensive health questionnaire, and were submitted to clinical and physical examinations. Bedridden individuals and/or those with severe cognitive impairment (n=20) were excluded. Cognitive status was assessed using the translated and validated version of the Mini-Mental State Examination (MMSE). The cutoff points for cognitive impairment was set as: 13 points for no schooling, 18 points for schooling from 1 to 11 years, and 26 points for more than 11 years of schooling. Additionally, 38 elders had technical problems during data recording, which limited their inclusion in the analysis. Data were collected between January and July 2015.

**Ethical aspects**

The individuals included in this study were informed about all the procedures and provided written informed consent to participate. This study was approved by the ethics committee of the institution (CAAE: 10786212.3.0000.0055) and abides by the CONEP resolution 466/2012.

**Definition of hypertension and depression**

The stratification of hypertensive and normotensive elderly subjects was based on previous diagnosis reported by the elders, while the stratification of depressive and non-depressive elders was based on the Geriatric Depression Scale (GDS), which was validated to the Brazilian population. The cut-off score for depression was set as 6 positive items.

The most commonly used psychotropic medications among depressive elders were tricyclic and selective serotonin-reuptake-inhibitors, benzodiazepines and muscle-relaxation drugs.

**Adjustment variables**

The dichotomous variables sex (male or female), race (white or non-white), smoking habit (yes or not), physical activity level (sufficiently active or insufficiently active), and self-reported diagnostic of DM (yes or no), and the continuous variables age and body mass index (BMI, Kg/m²) was used as adjustment variables.

Physical activity level was obtained using the International Physical Activity Questionnaire (IPAQ) and the results were dichotomized according to the proposed cut-point of ≥ 150 min/week of moderate and vigorous activity (i.e., ≥ 150 min/wk, sufficiently active; < 150 min/week, insufficiently active).

variables (sex, race, smoking habits, diabetes mellitus and physical activity) with hypertension.

Since the variables DM, BMI, and physical activity level were associated with hypertension and depression, logistic regression analysis was performed, with and without adjustments for the cited variables. Table 3 shows the regression coefficient, and the odds ratio (OR) and its 95% confidence interval of the variables included in the adjusted and unadjusted logistic regression analysis. It is possible that the association between hypertension and depression was directly influenced by BMI, and physical activity level, while the analysis adjusted for all the variables (DM, BMI and physical activity level) together also confirmed the significant influence of these variables on the relationship between depression and hypertension in community-dwelling elders.

Discussion

The present study aimed to analyze the association between depression and hypertension in community-dwelling elders, and to analyze the influence of potential confounding variables. Our results showed that the association between depression and hypertension was significantly influenced by BMI, physical activity level and DM.

In fact, no significant association was found between depression and hypertension (OR [95%CI] = 2.28 [0.98 - 5.32]; p = 0.06) when analyzed without adjustment variables. However, after adjustment for the variables BMI (OR [CI95%] = 2.66 [1.04 - 6.79], p = 0.04) and physical activity level (OR [CI95%] = 3.41 [1.31 - 8.85], p = 0.01) a significant association was found between depression and hypertension in the study population. The analysis adjusted for BMI, physical activity level and DM together also influenced significantly the association between depression and hypertension (OR [95%CI] = 3.08 [1.12 - 8.46]; p = 0.03).

In our study, DM was significantly associated with hypertension, but not with depression, which may explain the lack of influence of the adjustment for DM on the association between hypertension and depression. Previous studies have shown that DM is common among depressed people;16,17 in fact, in our study, 31.3% of depressed elderly people were diabetic, whereas this prevalence was only 18.8% among non-depressed elderly people. However, no significant difference was achieved. Despite this, the considerably higher prevalence of diabetic elderly among depressive and (statistically significant) hypertensive elders justifies the maintenance of this intervening variable (i.e., DM) in the regression model adjusted for DM, BMI and level of physical activity.

The close association of obesity with depression18,19 and hypertension20,21 explains the strong influence of this variable on the relationship between depression

and hypertension. Follow-up studies have corroborated such relationship, since the presence of obesity increases by 1.55 times the odds to develop depression, just as depression increases 1.58 times the odds to develop obesity. 18-22 Therefore, a higher cardiovascular risk comes from the association of these conditions, i.e., obesity and depression. 18,23

The adoption of a physically active lifestyle has been pointed out as an effective behavioral intervention to treat depression symptoms. 24-25 Josefsson et al., 26 in a systematic review with meta-analysis on this issue, concluded that the use of exercise as an intervention generates positive results in mild-to-moderate depression. Blake et al. 27 stated that physical activity programs can achieve positive results in the treatment of depressive symptoms in the elderly.

The recent study of Holmquist et al., 28 broadens the basis of these findings. In the cited study, the authors evaluated the association of depression with several lifestyle-related variables, previous illnesses and physical performance in the elderly. It was observed that depressed elders (GDS ≥ 5 points) were predominantly obese, diabetic, and physically less active (or had worse physical performance). In fact, these same variables may be associated with hypertension, and thus can influence the association between hypertension and depression. In this sense, two aspects are relevant: 1) the identification of depressive, obese, diabetic and insufficiently active elderly subjects can guide the screening of those prone to hypertension, since this set of factors among elders increases in 3.08 (1.12 - 8.46) times the odds of being hypertensive; 2) all the studied factors associated with hypertension and depression here are amenable to intervention; thus, as proposed by Blake et al., 27 preventive strategies focused on physical activity could represent an excellent strategy from the point of view of cost-effectiveness to prevent hypertension in depressed elderly people, since the level of physical activity increases 3.41 (1.31 - 8.85) times the odds of a depressed elderly subject being hypertensive.
Conclusion

Our results showed that BMI, DM and physical activity level influence the association between hypertension and depression in community-dwelling elders. DM affects the association between depression and hypertension when combined to physical activity and BMI. In addition, the level of physical activity seems to be the main influencing factor of this relationship. This promotes positive perspectives regarding therapeutic interventions, since, unlike drug interventions, the adoption of a physically active lifestyle is an excellent, cost-effective intervention for both hypertension and depression.
